

INTRODUCTION

Earth Observation (EO) techniques offer relevant data to integrate classical in situ limnological measurements aiming at frequent and synoptic monitoring of lakes. Within this study, EO data of deep clear lakes in the European subalpine ecoregion, which are showing a clear response to climate change with an increase of 0.017 °C/year of lake surface temperature¹, are exploited for understanding the changes of suspended sediments and energy fluxes in recent years. The investigation is focused on Lake Iseo, which has shown a significant deterioration of water quality conditions since the '70. Physic-based approach and field data are combined to derive LST, TSM, Evaporation rate and Heat storage from Landsat-8 images of the last three years. After the products validation, the technique is applied to Lake Garda. The results show the capability of Landsat-8 with its optical and thermal sensors, to investigate bio-physical parameters in the study area. This method will be extended to the ESA Sentinel-3 data, to increase the observations frequency.

Validation

Atmospheric correction and TSM products were validated on the basis of in situ measurements of Remote Sensing Reflectance RRS and TSM concentration collected during field campaigns on 2016 on Lake Iseo, synchronous to the satellite overpass. LST and R_n products were validated using in situ measurements of pelagic station in Lake Iseo belonging to UNIBS Hydraulic group.

	RMSE
TSM	0.25 mg/l
LST	1.82 K
R_n	158 W/m^2

Lake Garda

The same method was used, using Turbidity, Surface temperature and surface reflectance maps produced by EOMAP, through MIP processor, over Lake Garda. First results are shown.
